Abstract

Increasingly larger data sets of processes in space and time ask for statistical models and methods that can cope with such data. We show that solutions of stochastic advection-diffusion partial differential equations (SPDEs) provide a flexible model class for spatio-temporal processes which is computationally feasible also for large data sets. The solution of the SPDE has in general a nonseparable covariance structure. Furthermore, its parameters can be physically interpreted as explicitly modeling phenomena such as transport and diffusion that occur in many natural processes in diverse fields ranging from environmental sciences to ecology. In order to obtain computationally efficient statistical algorithms we use spectral methods to solve the SPDE. This has the advantage that approximation errors do not accumulate over time, and that in the spectral space the computational cost grows linearly with the dimension, the total computational costs of Bayesian or frequentist inference being dominated by the fast Fourier transform. The proposed model is applied to postprocessing of precipitation forecasts from a numerical weather prediction model for northern Switzerland. In contrast to the raw forecasts from the numerical model, the postprocessed forecasts are calibrated and quantify prediction uncertainty. Moreover, they outperform the raw forecasts.

1 Introduction

Space-time data arise in many applications, see Cressie and Wikle (2011) for an introduction and an overview. Increasingly larger space-time data sets are obtained, for instance, from remote sensing satellites or deterministic physical models such as numerical weather prediction (NWP) models. Statistical models are needed that can cope with such data.

As Wikle and Hooten (2010) point out, there are two basic paradigms for constructing spatio-temporal models. The first approach is descriptive and follows the traditional geostatistical paradigm, using joint space-time covariance functions (Cressie and Huang 1999; Gneiting 2002; Mal 2003; Wikle 2003; Stein 2005; Paciorek and Schervish 2006). The second approach is dynamic and combines ideas from time-series and spatial statistics (Solina and Switzer 1996; Wikle and Cressie 1999; Huang and Hsu 2004; Xu et al. 2005; Gelfand et al. 2005; Johannesson et al. 2007; Sigrist et al. 2012).

Even for purely spatial data, developing methodology which can handle large data sets is an active area of research. Banerjee et al. (2004) refer to this as the “big n problem”. Factorizing large covariance matrices is not possible without assuming a special structure or using approximate methods. Using low rank matrices is one approach (Nychka et al. 2002; Banerjee et al. 2008; Cressie and Johannesson 2008; Stein 2008; Wikle 2010). Other proposals include using Gaussian Markov random-fields (GMRF) (Rue and Tjelmeland 2002; Rue and Held 2005; Lindgren et al. 2011) or applying tapering (Furrer et al. 2006) so that one obtains sparse precision or covariance matrices, respectively, for which calculations can be done efficiently. Another proposed solution is to approximate the likelihood so that it can be evaluated faster (Vecchia 1988; Stein et al. 2004; Fuentes 2007; Eidsvik et al. 2012). Royle and Wikle (2005) and Paciorek (2007) use Fourier functions to reduce computational costs.

In a space-time setting, the situation is the same, if not worse: one runs into a computational bottleneck with high dimensional data since the computational costs to factorize dense $NT \times NT$ covariance matrices are $O((NT)^3)$, $N$ and $T$ being the number of points in space and time, respectively. Moreover, specifying flexible and realistic space-time covariance functions is a nontrivial task.

In this paper, we follow the dynamic approach and study models which are defined through a stochastic advection-diffusion partial differential equation (SPDE). This has the advantage of providing physically motivated parametrizations of space-time covariances. We show that when solving the SPDE using Fourier functions, one can do computationally efficient statistical inference. In the spectral space, computational costs for the Kalman filter and backward sampling algorithms are of order $O(NT)$. As we show, roughly speaking, this computational efficiency is due to the temporal Markov property, the fact that Fourier functions are eigenfunctions of the spatial differential operators, and the use of some matrix identities. The overall computational costs are then determined by the ones of the fast Fourier transform (FFT) (Cooley and Tukey 1965) which are $O(TN \log N)$.

Defining Gaussian processes through stochastic differential equations has a long history in statistics going back to early works such as Whittle (1954, 1955, 1962). Later works include Jones and Zhang (1997) and Brown et al. (2000). Recently, Lindgren et al. (2011) showed how a certain class of SPDEs can be solved using finite elements to obtain parametrizations of spatial GMRF.

Spectral methods for solving partial differential equation are well established in the numerical mathematics community (see, e.g., Gottlieb and Orszag (1977), Folland (1992), or Haberman (2004)). In contrast, statistical models have different requirements and goals, since
the (hyper-)parameters of an (S)PDE are not known a priori and need to be estimated. Spectral methods have also been used in spatio-temporal statistics, mostly for approximating or solving deterministic integro-difference equations (IDEs) or PDEs. Wikle and Cressie (1999) introduce a dynamic spatio-temporal model obtained from an IDE that is approximated using a reduced-dimensional spectral basis. Extending this work, Wikle (2002) and Xu et al. (2005) propose parametrizations of spatio-temporal processes based on IDEs. Modeling tropical ocean surface winds, Wikle et al. (2001) present a physics based model based on the shallow-water equations. See also (Cressie and Wikle 2011, Chapter 7) for an overview of basis function expansions in spatio-temporal statistics.

The novel features of our work are the following. While spectral methods have been used for approximating deterministic IDEs and PDEs in the statistical literature, there is no article, to our knowledge, that explicitly shows how one obtains a space-time Gaussian process by solving an advection-diffusion SPDE using the real Fourier transform. Moreover, we present computationally efficient algorithms, for doing statistical inference, which use the fast Fourier transform and the Kalman filter. The computational burden can be additionally alleviated by applying dimension reduction. We also give a bound on the accuracy of the approximate solution. In the application, we postprocess precipitation forecasts, explicitly modeling spatial and temporal variation. The idea is that the spatio-temporal model not only accounts for dependence, but it also captures and extrapolates dynamically an error term of the NWP model in space and time.

The remainder of this paper is organized as follows. Section 2 introduces the continuous space-time Gaussian process defined through the advection-diffusion SPDE. In Section 3, it is shown how the solution of the SPDE can be approximated using the two-dimensional real Fourier transform, and we give convergence rates for the approximation. Next, in Section 4, we show how one can do computationally efficient inference. In Section 5, the spatio-temporal model is used as part of a hierarchical Bayesian model, which we then apply for postprocessing of precipitation forecasts.

All the methodology presented in this article is implemented in the R package spate (see Sigrist et al. (2012)).

2 A Continuous Space-Time Model: The Advection-Diffusion SPDE

In one dimension, a fundamental process is the Ornstein-Uhlenbeck process which is governed by a relatively simple stochastic differential equation (SDE). The process has an exponential covariance function and its discretized version is the famous AR(1) model. In the two dimensional spatial case, Whittle (1954) argues convincingly that the process with a Whittle correlation function is an “elementary” process (see Section 2.2 for further discussion). If the time dimension is added, we think that the process defined through the stochastic partial differential equation (SPDE) in (1) has properties that make it a good candidate for an “elementary” spatio-temporal process. It is a linear equation that explicitly models phenomena such as transport and diffusion that occur in many natural processes ranging from environmental sciences to ecology. This means that, if desired, the parameters can be given a physical interpretation. Furthermore, if some parameters equal zero (no advection and no diffusion), its covariance structure reduces to a separable one with an AR(1) structure over time and a certain covariance structure over space.
The advection-diffusion SPDE, also called transport-diffusion SPDE, is given by
\[
\frac{\partial}{\partial t} \xi(t, s) = -\mu \cdot \nabla \xi(t, s) + \nabla \cdot \Sigma \nabla \xi(t, s) - \zeta \xi(t, s) + \epsilon(t, s),
\]
(1)
with \(s = (x, y)' \in \mathbb{R}^2\), where \(\nabla = \left( \frac{\partial}{\partial x}, \frac{\partial}{\partial y} \right)'\) is the gradient operator, and, for a vector field \(F = (F_x, F_y)'\), \(\nabla \cdot F = \frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y}\) is the divergence operator. \(\epsilon(t, s)\) is a Gaussian process that is temporally white and spatially colored. See Section 2.2 for a discussion on the choice of the spatial covariance function. The SPDE has the following interpretation. Heuristically, an SPDE specifies what happens locally at each point in space during a small time step. The first term \(\mu \cdot \nabla \xi(t, s)\) models transport effects (called advection in weather applications), \(\mu = (\mu_x, \mu_y)'\) being a drift or velocity vector. The second term, \(\nabla \cdot \Sigma \nabla \xi(t, s)\), is a diffusion term that can incorporate anisotropy. If \(\Sigma\) is the identity matrix, this term reduces to the divergence \((\nabla \cdot)\) of the gradient \((\nabla)\) which is the ordinary Laplace operator \(\nabla \cdot \nabla = \Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\). The third term \(-\zeta \xi(t, s)\) diminishes \(\xi(t, s)\) at a constant rate and thus accounts for damping. Finally, \(\epsilon(t, s)\) is a source-sink or stochastic forcing term, also called innovation term, that can be interpreted as describing, amongst others, convective phenomena in precipitation modeling applications.

Concerning the diffusion matrix \(\Sigma\), we suggest the following parametrization
\[
\Sigma^{-1} = \frac{1}{p_1^2} \begin{pmatrix}
\cos \alpha & \sin \alpha \\
-\gamma \cdot \sin \alpha & \gamma \cdot \cos \alpha
\end{pmatrix}^T \begin{pmatrix}
\cos \alpha & \sin \alpha \\
-\gamma \cdot \sin \alpha & \gamma \cdot \cos \alpha
\end{pmatrix}.
\]
(2)
The parameters are interpreted as follows. \(p_1\) acts as a range parameter and controls the amount of diffusion. The parameters \(\gamma\) and \(\alpha\) control the amount and the direction of anisotropy. With \(\gamma = 1\), isotropic diffusion is obtained.

Heine (1955) and Whittle (1963) introduced and analyzed SPDEs of similar form as in (1). Further, Jones and Zhang (1997) also investigated SPDE based models. Brown et al. (2000) obtained such an advection-diffusion SPDE as a limit of stochastic integro-difference equation models. Without giving any concrete details, Lindgren et al. (2011) suggested that this SPDE can be used in connection with their GMRF method.

Figure 1 illustrates the SPDE in (1) and the corresponding PDE without the stochastic innovation term. The top row shows a solution to the PDE which corresponds the deterministic part of the SPDE that is obtained when there is no stochastic term \(\epsilon(t, s)\). The figure shows how the initial state in the top-left plot gets propagated forward in time. The drift vector points from north-east to south-west and the diffusive part exhibits anisotropy in the same direction. A 100 \(\times\) 100 grid is used and the PDE is solved in the spectral domain using the method described below in Section 3. There is a fundamental difference between the deterministic PDE and the probabilistic SPDE. In the first case, a deterministic process is modeled directly. In the second case, the SPDE defines a stochastic process. Since the operator is linear and the input Gaussian, this process is a Gaussian process whose covariance function is implicitly defined by the SPDE. The bottom row of Figure 1 shows one sample from this Gaussian process. The same initial state as in the deterministic example is used, i.e., we use a fixed initial state. For the innovations \(\epsilon(t, s)\), we choose a Gaussian process that is temporally independent and spatially structured according to the Matérn covariance function with smoothness parameter 1. Again, the drift vector points from north-east to south-west and the diffusive part exhibits anisotropy in the same direction.
Figure 1. Illustration of the SPDE in (1) and the corresponding PDE. The top row illustrates a solution to the PDE which corresponds the deterministic part of the SPDE without stochastic term \( \epsilon(t, s) \). The bottom row shows one sample from the distribution specified by the SPDE with a fixed initial condition. The drift vector points from north-east to south-west and the diffusive part exhibits anisotropy in the same direction.

Note that the use of this spatio-temporal Gaussian process is not restricted to situations where it is a priori known that phenomena such as transport and diffusion occur. In the one dimensional case, it is common to use the AR(1) process in situations where it is not a priori clear whether the modeled process follows the dynamic of the Ornstein-Uhlenbeck SDE. In two dimensions, the same holds true for the process with the Whittle covariance function, not to mention the process having an exponential covariance structure. Having this in mind, even though the SPDE in (1) is physically motivated, it can be used as a general spatio-temporal model. As the case may be, the interpretation of the parameters can be more or less straightforward.

2.1 Spectral Density and Covariance Function

As can be shown using the Fourier transform (see, e.g., Whittle [1963]), if the innovation process \( \epsilon(t, s) \) is stationary with spectral density \( \hat{f}(k) \), the spectrum of the stationary solution \( \xi(t, s) \) of the SPDE (1) is

\[
f(\omega, k) = \hat{f}(k) \frac{1}{(2\pi)} \left( (k' \Sigma k + \zeta)^2 + (\omega + \mu' k)^2 \right)^{-1},
\]

where \( k \) and \( \omega \) are spatial wavenumbers and temporal frequencies. The covariance function \( C(t, s) \) of \( \xi(t, s) \) is then given by

\[
C(t, s) = \int f(\omega, k) \exp(it\omega) \exp(is'k) dk d\omega
= \int \hat{f}(k) \exp \left( -i\mu' k t - (k' \Sigma k + \zeta)|t| \right) \exp(is'k) dk,
\]

where the integration over the temporal frequencies \( \omega \) follows from the calculation of the characteristic function of the Cauchy distribution (Abramowitz and Stegun [1964]). The spatial
integral above has no closed form solution but can be computed approximately by numerical integration.

Since, in general, the spectrum does not factorize into a temporal and a spatial component, we see that \(\xi(t, s)\) has a non-separable covariance function (see Gneiting et al. (2007b) for a definition of separability). The model reduces to a separable one, though, when there is no advection and diffusion, i.e., when both \(\mu\) and \(\Sigma\) are zero. In this case, the covariance function is given by

\[
C(t, s) = \frac{1}{\zeta} \exp \left(-\zeta |t|\right) C(s),
\]

where \(C(s)\) denotes the spatial covariance function of the innovation process.

### 2.2 Specification of the Innovation Process

As mentioned before, it is assumed that the innovation process is white in time and spatially colored. In principle, one can choose any spatial covariance function such that the covariance function in (4) is finite at zero. Note that if \(\hat{f}(k)\) is integrable, then \(f(\omega, k)\) is also integrable. Similarly as Lindgren et al. (2011), we opt for the most commonly used covariance function in spatial statistics: the Matérn covariance function (see Handcock and Stein (1993), Stein (1999)). Since in many applications the smoothness parameter is not estimable, we further restrict ourselves to the Whittle covariance function. This covariance function is of the form

\[
\sigma^2 \frac{d}{\rho_0} K_1 \left(\frac{d}{\rho_0}\right)
\]

with \(d\) being the Euclidean distance between two points and \(K_1 \left(\frac{d}{\rho_0}\right)\) being the modified Bessel function of order 1. It is called after Whittle (1954) who introduced it and argued convincingly that it “may be regarded as the ‘elementary’ correlation in two dimensions, similar to the exponential in one dimension.”. It can be shown that the stationary solution of the SPDE

\[
\left(\nabla \cdot \nabla - \frac{1}{\rho_0^2}\right) \epsilon(t, s) = W(t, s),
\]

where \(W(t, s)\) is a zero mean Gaussian white noise field with variance \(\sigma^2\), has the Whittle covariance function in space. From this, it follows that the spectrum of the process \(\epsilon(t, s)\) is given by

\[
\hat{f}(k) = \frac{\sigma^2}{(2\pi)^2} \left(k^T k + \frac{1}{\rho_0^2}\right)^{-2}.
\]

### 2.3 Relation to an Integro-Difference Equation

Assuming discrete time steps with lag \(\Delta\), Brown et al. (2000) consider the following integro-difference equation (IDE)

\[
\xi(t, s) = \exp \left(-\Delta \zeta\right) \int_{\mathbb{R}^2} h(s - s') \xi(t - \Delta, s') ds' + \epsilon(t, s), \quad s \in \mathbb{R}^2,
\]

with a Gaussian redistribution kernel

\[
h(s - s') = (2\pi)^{-1} |2\Delta \Sigma|^{-1/2} \exp \left(- (s - s' - \Delta \mu)^T (2\Delta \Sigma)^{-1} (s - s' - \Delta \mu)/2\right),
\]

\(\epsilon(t, s)\) being temporally independent and spatially dependent. They show that in the limit \(\Delta \to 0\), the solution of the IDE and the one of the SPDE in (1) coincide. The IDE is interpreted as follows: the convolution kernel \(h(s - s')\) determines the weight or the amount of influence that a location \(s'\) at previous time \(t - \Delta\) has on the point \(s\) at current time \(t\). This IDE representation provides an alternative way of interpreting the SPDE model and its
parameters. Storvik et al. (2002) show under which conditions a dynamic model determined by an IDE as in (7) can be represented using a parametric joint space-time covariance function, and vice versa. Based on the IDE in (7), Sigrist et al. (2012) construct a spatio-temporal model for irregularly spaced data and apply it to obtain short term predictions of precipitation.

3 Solution in the Spectral Space

Solutions $\xi(t, s)$ of the SPDE (1) are defined in continuous space and time. In practice, one needs to discretize both space and time. The resulting vector of $NT$ space-time points is in general of large dimension. This makes statistical inference, be it frequentist or Bayesian, computationally difficult to impossible. However, as we show in the following, solving the SPDE in the spectral space alleviates the computational burden considerably and allows for dimension reduction, if desired.

Heuristically speaking, spectral methods (Gottlieb and Orszag [1977], Cressie and Wikle [2011] [Chapter 7]) approximate the solution $\xi(t, s)$ by a linear combination of deterministic spatial functions $\phi_j(s)$ with random coefficients $\alpha_j(t)$ that evolve dynamically over time:

$$
\xi^K(t, s) = \sum_{j=1}^{K} \alpha_j(t) \phi_j(s) = \phi(s)'\alpha(t),
$$

where $\phi(s) = (\phi_1(s), \ldots, \phi_K(s))'$ and $\alpha(t) = (\alpha_1(t), \ldots, \alpha_K(t))'$. As we argue below, it is expedient to use Fourier functions

$$
\phi_j(s) = \exp(i k_j' s),
$$

where $i$ denotes the imaginary number $i^2 = -1$ and $k_j = (k_{jx}, k_{jy})'$ is a spatial wavenumber.

For solving the SPDE in (1), Fourier functions have several advantages. First, differentiation in the physical space corresponds to multiplication in the spectral space. In other words, Fourier functions are eigenfunctions of the spatial differential operator. Instead of approximating the differential operator in the physical space and then worrying about approximation errors, one just has to multiply in the spectral space, and there is no approximation error of the operator. Further, the solution of the SPDE is exact over time, given the frequencies included, see Proposition 1 below. In contrast to finite differences, one does not accumulate errors over time. The approximation error only depends on the number of spectral terms and not on the temporal discretization. This is related to the fact that there is no need for numerical stability conditions. For statistical applications, where the parameters are not known a priori, this is particularly useful. Finally, one can use the FFT for efficiently transforming from the physical to the spectral space, and vice versa. However, since Fourier terms are global functions, stationarity in space but not in time is a necessary assumption.

The following result shows that if the initial condition and the innovation process are in the space spanned by a finite number of Fourier functions, then the solution of the SPDE in (1) remains in this space for all times and can be given in explicit form.

Proposition 1. Assume that the initial state and the innovation terms are of the form

$$
\xi^K(0, s) = \phi(s)'\alpha(0), \quad \epsilon^K(t, s) = \phi(s)'^\epsilon(t)
$$

(10)
where $\phi(s) = (\phi_1(s), \ldots, \phi_K(s))'$, $\phi_j(s)$ is given in 9 and $\tilde{\epsilon}(t)$ is a $K$-dimensional Gaussian white noise independent of $\alpha(0)$ with

$$\text{Cov}(\tilde{\epsilon}(t), \tilde{\epsilon}(t')) = \delta_{t,t'} \text{diag}\left(\hat{f}(k_j)\right),$$

(11)

where $\hat{f}$ is a spectral density. Then the process $\xi^K(t, s) = \phi(s)'^\alpha(t)$ where the components $\alpha_j(t)$ are given by

$$\alpha_j(t) = \exp(h_j t)\alpha_j(0) + \int_0^t \exp(h_j(t-s))\hat{\epsilon}_j(s)ds$$

(12)

with $h_j = -i\mu'k_j - k'_j \Sigma k_j - \zeta$ is a solution of the SPDE in [1]. For $t \to \infty$, the influence of the initial condition $\exp(h_j t)\alpha_j(0)$ converges to zero and the process $\xi(t, s)$ converges to a stationary Gaussian process with mean zero and

$$\text{Cov}(\xi^K(t + \Delta t, s), \xi^K(t, s')) = \phi(s)'\text{diag}\left(\frac{-\exp(h_j \Delta t)\hat{f}(k_j)}{h_j + h_j^*}\right)\phi(s')^*,$$

where $^*$ stands for complex conjugation.

**Proof of Proposition 1.** By (12), we have

$$\frac{\partial}{\partial t} \xi^K(t, s) = \sum_{j=1}^K \hat{\alpha}_j(t)\phi_j(s) = \sum_{j=1}^K (h_j \alpha_j(t) + \hat{\epsilon}_j(t))\phi_j(s).$$

On the other hand, since the functions $\phi_j(s) = \exp(i\mathbf{k}_j's)$ are Fourier terms, differentiation in the physical space corresponds to multiplication in the spectral space:

$$\mathbf{\mu} \cdot \nabla \phi_j(s) = i\mathbf{\mu}'k_j\phi_j(s)$$

(13)

and

$$\nabla \cdot \Sigma \nabla \phi_j(s) = -k'_j \Sigma k_j \phi_j(s).$$

(14)

Therefore, by the definition of $h_j$,

$$(-\mathbf{\mu} \cdot \nabla + \nabla \cdot \Sigma \nabla - \zeta) \sum_{j=1}^K \alpha_j(t)\phi_j(s) = \sum_{j=1}^K h_j \alpha_j(t)\phi_j(s).$$

Together, we have

$$\frac{\partial}{\partial t} \xi^K(t, s) = (-\mathbf{\mu} \cdot \nabla + \nabla \cdot \Sigma \nabla - \zeta) \xi^K(t, s) + \epsilon^K(t, s)$$

which proves the first part of the proposition. Since the real part of $h_j$ is negative, $\exp(h_j t) \to 0$ for $t \to \infty$. Moreover,

$$\lim_{t \to \infty} \text{Cov}(\alpha_j(t + \Delta t), \alpha_j(t)) = \lim_{t \to \infty} \exp(h_j \Delta t)\delta_{j,j}\hat{f}(k_j) \int_0^t \exp(-(h_j + h_j^*)(t-s))ds$$

$$= -\frac{\exp(h_j \Delta t)}{h_j + h_j^*} \delta_{j,j}\hat{f}(k_j),$$

(15)

and thus the last statement follows.
We assume that the forcing term $\epsilon(t, \cdot)$, and consequently also the solution $\xi(t, \cdot)$, is stationary in space. Recall the Cramér representation for a stationary field $\epsilon(t, \cdot)$

$$
\epsilon(t, s) = \int \exp(ik's)\hat{d}_t(k)
$$

where $\hat{d}_t$ has orthogonal increments $\text{Cov}(\hat{d}_t(k), \hat{d}_t'(l)) = \delta_{l,l'}\hat{\delta}_{k,l}\hat{f}(k)$ and $\hat{f}$ is the spectral density of $\epsilon(t, \cdot)$ (see, e.g., [Cramér and Leadbetter (1967)]). This implies that we can approximate any stationary field, in particular also the one with a Whittle covariance function, by a finite linear combination of complex exponentials, and the covariance of $\hat{d}(t)$ is a diagonal matrix as required in the proposition.

### 3.1 Approximation bound

By passing to the limit $K \to \infty$ such that both the wavenumbers $k_j$ cover the entire domain $\mathbb{R}^2$ and the distance between neighboring wavenumbers goes to zero, we obtain from [5] the stationary (in space and time) solution with spectral density as in (3). In practice, if one uses the discrete Fourier transform (DFT), or its fast variant, the FFT, the wavenumbers are regularly spaced and the distance between them is fixed for all $K$ (see below). This implies that the covariance function of an approximate solution is periodic which is equivalent to assuming a rectangular domain being wrapped around a torus. Since in most applications, the domain is fixed anyway, this is a reasonable assumption.

Based on the above considerations, we assume, in the following, that $s \in [0, 1]^2$ with periodic boundary condition, i.e., that $[0, 1]^2$ is wrapped on a torus. In practice, to avoid spurious periodicity, we can apply what is called “padding”. This means that we take $s \in [0, 0.5]^2$ and then embed it in $[0, 1]^2$. As in the discrete Fourier transform, if we choose $s \in [0, 1]^2$, it follows that the spatial wavenumbers $k_j$ lie on the $n \times n$ grid given by $D_n = \{2\pi \cdot (i, j) : -(n/2 + 1) \leq i, j \leq n/2\} = \{-2\pi(n/2 + 1), \ldots, 2\pi n/2\}^2$ with $n^2 = N = K$, $n$ being an even natural number. We then have the following convergence result.

**Proposition 2.** The approximation $\xi^N(t, s)$ converges in law to the solution $\xi(t, s)$ of the SPDE (1) with $s \in [0, 1]^2$ wrapped on a torus, and we have the bound

$$
|C(t, s) - C^N(t, s)| \leq \sigma^2 - \hat{\sigma}^2_N, \quad (16)
$$

where $C(t, s)$ and $C^N(t, s)$ denote the covariance functions of $\xi(t, s)$ and $\xi^N(t, s)$, respectively, and where $\sigma^2 = C(0, 0)$ and $\hat{\sigma}^2_N = C^N(0, 0)$ denote the marginal variances of these two processes.

**Proof of Proposition 2.** Similarly as in (4) and due to $k \in 2\pi \cdot \mathbb{Z}^2$, it follows that covariance function of $\xi(t, s)$ is given by

$$
C(t, s) = \sum_{k \in 2\pi \cdot \mathbb{Z}^2} \int f(\omega, k)\exp(it\omega)d\omega \exp(is'k)
$$

$$
= \sum_{k \in 2\pi \cdot \mathbb{Z}^2} \hat{f}(k)\frac{-\exp(h_{kt})}{h_k + h^*_{k}}\exp(is'k), \quad (17)
$$
where \( h_k = -i\mu' k - k'\Sigma k - \zeta \). From Proposition 1 we know that the approximate solution \( \xi^N(t, s) \) has the covariance function

\[
C^N(t, s) = \sum_{k \in D_n} \hat{f}(k) \frac{-\exp(h_k t)}{h_k + h_k^*} \exp(i s' k).
\]

It follows that

\[
|C(t, s) - C^N(t, s)| = \left| \sum_{k \in 2\pi \mathbb{Z}^2} \hat{f}(k) \frac{\exp(h_k t)}{h_k + h_k^*} (1 - \mathbb{1}(k \in D_n)) \exp(i s' k) \right| \leq \sum_{k \in 2\pi \mathbb{Z}^2} \hat{f}(k) \frac{1}{h_k + h_k^*} (1 - \mathbb{1}(k \in D_n)) = \sigma^2_\xi - \sigma^2_\xi^N.
\]

Not surprisingly, this result tells us that the rate of convergence essentially depends on the smoothness properties of the process \( \xi(t, s) \), i.e., on how fast the spectrum decays. The smoother \( \xi(t, s) \), that is, the more variation is explained by low frequencies, the faster is the convergence of the approximation.

Note that, there is a conceptual difference between the stationary solution of the SPDE (1) with \( s \in \mathbb{R}^2 \) and the periodic one with \( s \in [0, 1]^2 \) wrapped on a torus. For the sake of notational simplicity, we have denoted both of them by \( \xi(t, s) \). The finite dimensional solution \( \xi^N(t, s) \) is an approximation to both of the above infinite dimensional solutions. The above convergence result, though, only holds true for the solution on the torus.

### 3.2 Real Fourier Functions and Discretization in Time and Space

In order that we can apply the model to real data, we have to discretize it. In the following, we consider the process \( \xi(t, s) \) on a regular grid of \( n \times n = N \) spatial locations \( s_1, \ldots, s_N \) in \([0, 1]^2\) and at equidistant time points \( t_1, \ldots, t_T \) with \( t_i - t_{i-1} = \Delta \). Note that these two assumptions can be easily relaxed, i.e., one can have irregular spatial observation locations and non-equidistant time points. The former can be achieved by adopting a data augmentation approach (see, for instance, Sigrist et al. (2012)) or by using an incidence matrix (see Section 4.2). The latter can be done by taking a time varying \( \Delta \).

For the sake of illustration, we have stated the results in the previous section using complex Fourier functions. However, when discretizing the model, one obtains a linear Gaussian state space model with a propagator matrix \( G \) that contains complex numbers, due to (13). To avoid this, we replace the complex terms \( \exp(i k' j s) \) with real \( \cos(k' j s) \) and \( \sin(k' j s) \) functions. In other words, we use the real instead of the complex Fourier transform. The above results then still hold true, since for real valued data, the real Fourier transform is equivalent to the complex one. For notational simplicity, we will drop the superscript \( ^K \) from \( \xi^K(t, s) \). The distinction between the approximation and the true solution is clear from the context.

**Proposition 3.** On the above specified discretized spatial and temporal domain and using the real Fourier transform, a stationary solution of the SPDE (1) is of the form

\[
\xi(t_{i+1}) = \Phi \alpha(t_{i+1}),
\]

\[
\alpha(t_{i+1}) = G \alpha(t_i) + \tilde{\epsilon}(t_{i+1}), \quad \tilde{\epsilon}(t_{i+1}) \sim N(0, \tilde{Q}),
\]

where \( \Phi = \frac{1}{\Delta} \left( \sum_{k \in D_n} \hat{f}(k) \frac{-\exp(h_k t_1)}{h_k + h_k^*} \right) \).

\[
\tilde{Q} = \left( \sum_{k \in D_n} \hat{f}(k) \frac{1}{h_k + h_k^*} (1 - \mathbb{1}(k \in D_n)) \right)^{-1}.
\]

\[
\hat{f}(k) = \frac{1}{\Delta^2} \sum_{j=1}^N \sum_{s \in [0, 1]^2} \sin(k' j s) \xi(s).
\]

\[
\sigma^2_\xi = \frac{1}{\Delta^2} \sum_{j=1}^N \sum_{s \in [0, 1]^2} \sin^2(k' j s) \xi(s).
\]

\[
\sigma^2_\xi^N = \frac{1}{\Delta^2} \sum_{j=1}^N \sum_{s \in [0, 1]^2} \sin^2(k' j s) \xi^N(s).
\]
Now real Fourier transform of the random coefficients with parametric propagator matrix in (21). The above equations (20) and (21) form a linear Gaussian state space model and the Fourier coefficients with stacked vectors \( \xi(t) = (\xi(t, s_1), \ldots, \xi(t, s_N))' \) and cosine and sine coefficients \( \alpha(t) = (\alpha_1^{(c)}(t), \ldots, \alpha_4^{(c)}(t), \alpha_5^{(s)}(t), \alpha_6^{(s)}(t), \ldots, \alpha_{K/2+2}^{(c)}(t), \alpha_{K/2+2}^{(s)}(t))' \), where \( \Phi \) applies the discrete, real Fourier transformation, \( G \) is a block diagonal matrix with 2 \( \times \) 2 blocks, and \( \hat{Q} \) is a diagonal matrix. These random vectors are defined as follows.

\begin{itemize}
  \item \( \Phi = [\phi(s_1), \ldots, \phi(s_N)]' \),
  \[\phi(s_l) = (\phi_1^{(c)}(s_l), \ldots, \phi_4^{(c)}(s_l), \phi_5^{(s)}(s_l), \ldots, \phi_{K/2+2}^{(c)}(s_l), \phi_{K/2+2}^{(s)}(s_l))' \],
  \[\phi_j^{(c)}(s_l) = \cos(k_j's_l), \quad \phi_j^{(s)}(s_l) = \sin(k_j's_l), \]
  \item \( |G|_{1:4,1:4} = \text{diag}(\exp(-\Delta (k_j'^\prime \Sigma k_j + \zeta))) \),
  \[|G|_{5:K,5:K} = \text{diag}(\exp(-\Delta (k_j'^\prime \Sigma k_j + \zeta)) (\cos(\Delta \mu'^\prime k_j)1_2 - \sin(\Delta \mu'^\prime k_j) J_2)), \]
\end{itemize}

where

\[
\begin{bmatrix}
    1 & 0 \\
    0 & 1
\end{bmatrix}
\quad 
\begin{bmatrix}
    0 & 1 \\
    -1 & 0
\end{bmatrix}
\]

In summary, at each time point \( t \) and spatial point \( s \) the solution \( \xi(t, s) \) is the discrete real Fourier transform of the random coefficients \( \alpha(t) \)

\[
\xi(t, s) = \sum_{j=1}^{4} \alpha_j^{(c)}(t) \phi_j^{(c)}(s) + \sum_{j=5}^{K/2+2} \alpha_j^{(s)}(t) \phi_j^{(s)}(s) 
\]

\[= \phi(s)' \alpha(t), \]

and the Fourier coefficients \( \alpha(t) \) evolve dynamically over time according to the vector autoregression in (21). The above equations (20) and (21) form a linear Gaussian state space model with parametric propagator matrix \( G \) and innovation covariance matrix \( \hat{Q} \), the parametrization being determined by the corresponding SPDE.

**Proof of Proposition** Using

\[
\mu \cdot \nabla \phi_j^{(c)}(s) = i \mu'^\prime k_j \phi_j^{(s)}(s), \quad \mu \cdot \nabla \phi_j^{(s)}(s) = -i \mu'^\prime k_j \phi_j^{(c)}(s),
\]

\[
\nabla \cdot \Sigma \nabla \phi_j^{(c)}(s) = -k_j' \Sigma k_j \phi_j^{(c)}(s), \quad \nabla \cdot \Sigma \nabla \phi_j^{(s)}(s) = -k_j' \Sigma k_j \phi_j^{(s)}(s),
\]

and the same arguments as in the proof of Proposition [1] it follows that the continuous time solution is of the form [23]. For each pair of cosine - sine coefficients \( \alpha_j(t) = (\alpha_j^{(c)}(t), \alpha_j^{(s)}(t))' \) we have

\[
\alpha_j(t) = e^{H_j't} \alpha_j(0) + \int_0^t e^{H_j'(t-s)} \xi_j(s) ds,
\]

\[\text{where}
H_j = \begin{pmatrix}
-k_j' \Sigma k_j - \zeta & -\mu'^\prime k_j \\
\mu' k_j & -k_j' \Sigma k_j - \zeta
\end{pmatrix},
\]

Now \( H_j \) can be written as

\[
H_j = (k_j'^\prime \Sigma k_j - \zeta) 1_2 - \mu'^\prime k_j J_2,
\]

11
where
\[ 1_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad J_2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}. \]

Since \(1_2\) and \(J_2\) commute, we have
\[
e^{J_2 t} = \exp \left( -t(k_j' \Sigma k_j + \zeta) \right) 1_2 \exp \left( -t \mu' k_j J_2 \right) = \exp \left( -t(k_j' \Sigma k_j + \zeta) \right) \left( \cos(t \mu' k_j) 1_2 - \sin(t \mu' k_j) J_2 \right).
\]

Further, the covariance of the stochastic integral in (24) is given by
\[
\int_0^t e^{H_j(t-s)} \hat{f}(k_j) e^{H_j(t-s)} ds = \int_0^t \hat{f}(k_j) \exp \left( -2(k_j' \Sigma k_j + \zeta)(t-s) \right) 1_2 ds
= \hat{f}(k_j) \frac{1 - \exp \left( -2(k_j' \Sigma k_j + \zeta)t \right)}{2(k_j' \Sigma k_j + \zeta)} 1_2.
\]

Discretizing in time and space then leads to the result in (20) and (21).

![Spatial wavenumbers](image)

**Figure 2.** Illustration of spatial wavenumbers for the two-dimensional discrete real Fourier transform with \(n^2 = 400\) grid points.

The discrete complex Fourier transform uses \(n^2\) different wavenumbers \(k_j\), each having a corresponding Fourier term \(\exp(ik_j's)\). The real Fourier transform, on the other hand, uses \(n^2/2 + 2\) different wavenumbers, where four of them have only a cosine term and the others each have sine and cosine terms. This follows from the fact that, for real data, certain coefficients of the complex transform are the complex transpose of other coefficients. For technical details on the real Fourier transform, we refer to [Dudgeon and Mersereau (1984), Borgman et al. (1984), Royle and Wikle (2005), and Paciorek (2007)]. Figure 2 illustrates an example of the spatial wavenumbers, with \(n^2 = 20 \times 20 = 400\) grid points. The dots with a circle represent the wavenumbers actually used in the real Fourier transform, and the red
crosses mark the wavenumbers having only a cosine term. Note that in (23) we choose to order the spatial wavenumbers such that the first four spatial wavenumbers correspond to the cosine-only terms. To get an idea how the basis functions $\cos(k_\| s)$ and $\sin(k_\| s)$ look like, we plot in Figure 3 twelve low-frequency basis functions corresponding to the six spatial frequencies closest to the origin 0 (see Figure 2). Further, in Figure 4 there is an example of a propagator matrix $G$ when $n = 4$, i.e., when sixteen ($4^2$) spatial basis functions are used. The upper left $4 \times 4$ diagonal matrix corresponds to the cosine-only frequencies. The $2 \times 2$ blocks following correspond to wavenumbers with cosine - sine pairs.

Figure 3. Illustration of two dimensional Fourier basis functions used in the discrete real Fourier transform with $n^2 = 400$. On the x- and y-axis are the coordinates of $s$.

Figure 4. Illustration of propagator matrix $G$. 16 real Fourier functions are used ($n = 4$).
3.3 Remarks on Finite Differences

Another approach to solve PDEs or SPDEs such as the one in (1) consists of using a discretization such as finite differences. Stroud et al. (2010) use finite differences to solve an advection-diffusion PDE. Other examples are Wikle (2003), Xu and Wikle (2007), Duan et al. (2009), Malmberg et al. (2008), and Zheng and Aukema (2010). The finite difference approximation, however, has several disadvantages. First, each spatial discretization effectively implies an interaction structure between temporal and spatial correlation. In other words, as Xu et al. (2005) state, the discretization effectively suggests a knowledge of the scale of interaction, lagged in time. Usually, this space-time covariance interaction structure is not known, though. Furthermore, there are numerical stability conditions that need to be fulfilled in order that the approximate solution is meaningful. Since these conditions depend on the values of the unknown parameters, one can run into problems.

In addition, computational tractability is an issue. In fact, we have tried to solve the SPDE in (1) using finite differences as described in the following. A finite difference approximations in (1) leads to a vector autoregressive model with a sparse propagator matrix being determined by the discretization. The innovation term $\epsilon$ can be approximated using a Gaussian Markov random field with sparse precision matrix (see Lindgren et al. (2011)). Even though the propagator and the precision matrices of the innovations are sparse, we have run into a computational bottleneck when using the Forward Filtering Backward Sampling (FFBS) algorithm (Carter and Kohn 1994; Frühwirth-Schnatter 1994) for fitting the model. The basic problem is that the Kalman gain is eventually a dense matrix. Alternative sampling schemes like the information filter (see, e.g., Anderson and Moore (1979) and Vivar and Ferreira (2009)) did not solve the problem either. However, future research on this topic might come up with solutions.

4 Computationally Efficient Statistical Inference

As said in the introduction, when using a naive approach, the computational costs for a spatio-temporal model with $T$ time points and $N$ spatial points equal $O((NT)^3)$. Using the Kalman filter or the Forward Filtering Backward Sampling (FFBS) algorithm (Carter and Kohn 1994; Frühwirth-Schnatter 1994), depending on what is needed, these costs are reduced to $O(TN^3)$ which, generally, is still too high for large data sets. In the following, we show how Bayesian and frequentist inference can be done efficiently in $O(TN \log N)$ operations. In the spectral space, the costs of the algorithms grow linearly in the dimension $TN$, which means that the total computational costs are dominated by the costs of the fast Fourier transform (FFT) (Cooley and Tukey 1965) which are $O(TN \log N)$.

As is often done in a statistical model, we add a non-structured Gaussian term $\nu(t_{i+1}, s) \sim N(0, \tau^2)$, iid, to (20) to account for small scale variation and / or measurement errors. In geostatistics, this term is called nugget effect. Denoting the observations at time $t_i$ by $w(t_i)$, we then have the following linear Gaussian state space model:

$$w(t_{i+1}) = \Phi \alpha(t_{i+1}) + \nu(t_{i+1}), \quad \nu(t_{i+1}) \sim N(0, \tau^2 1_N), \quad (25)$$

$$\alpha(t_{i+1}) = G \alpha(t_i) + \tilde{\epsilon}(t_{i+1}), \quad \tilde{\epsilon}(t_{i+1}) \sim N(0, \tilde{Q}).$$

Note that $\xi(t_{i+1}) = \Phi \alpha(t_{i+1})$. As mentioned before, irregular spatial data can be modeled by adopting a data augmentation approach (see Sigrist et al. (2012)) or by using an incidence
matrix (see Section 4.2). For the sake of simplicity, a zero mean was assumed. Extending the model by including covariates in a regression term is straightforward. Furthermore, we assume normality. The model can be easily generalized to allow for data not following a Gaussian distribution. For instance, this can be done by including it in a hierarchical Bayesian model (HBM) \cite{wikle1998} and specifying a non-Gaussian distribution for \( w | \xi \). A frequentist approach is then typically no longer feasible. But approximate posterior probabilities can still be computed using, for instance, simulation based methods such as Markov chain Monte Carlo (MCMC) \cite{gilks1996,robert2004}. An additional advantage of BHMs is that these models can be extended, for instance, to account for temporal nonstationarity by letting one or several parameters vary over time.

### 4.1 Kalman Filtering and Backward Sampling in the Spectral Space

In a frequentist context, it is crucial that one is able to evaluate the likelihood with a reasonable computational effort, and when doing Bayesian inference, one needs to be able to simulate efficiently from the full conditional of the latent process \( \xi \). Below, we show how both these tasks can be done in the spectral space in linear time, i.e., using \( O(TN) \) operations. For transforming between the physical and spectral space, one can use the FFT which requires \( O(TN \log N) \) operations. We start with the spectral version of the Kalman filter. Its output is used for both evaluating the log-likelihood and for simulating from the full conditional of the coefficients \( \alpha \).

\begin{algorithm}[h]
\caption{Spectral Kalman filter}
\label{alg:kalman_spectrum}
\begin{algorithmic}
\State \textbf{Input:} \( T, \hat{\omega}, G, \tau^2, \hat{Q}, H \)
\State \textbf{Output:} forecast and filter means \( m_{t_i|t_{i-1}}, m_{t_i|t_i} \) and covariance matrices \( R_{t_i|t_{i-1}}, R_{t_i|t_{i-1}}, i = 1, \ldots, T \)
\State \( m_{t_0|t_0} = 0 \)
\State \( R_{t_0|t_0} = \hat{Q} \)
\For {i = 1 to T}
\State \( m_{t_i|t_{i-1}} = Gm_{t_i-1|t_{i-1}} \)
\State \( R_{t_i|t_{i-1}} = \hat{Q} + R_{t_{i-1}|t_{i-1}}H \)
\State \( R_{t_i|t_i} = (\tau^{-2}1_N + R_{t_{i-1}|t_{i-1}})^{-1} \)
\State \( m_{t_i|t_i} = m_{t_i|t_{i-1}} + \tau^{-2}R_{t_i|t_i}(\hat{w}(t_i) - m_{t_i|t_{i-1}}) \)
\EndFor
\end{algorithmic}
\end{algorithm}

Algorithm \ref{alg:kalman_spectrum} shows the Kalman filter in the spectral space. For the sake of simplicity, we assume that the initial distribution equals the innovation distribution. The spectral Kalman filter has as input the Fourier transform of \( \hat{\omega} = (\hat{\omega}(t_1)', \ldots, \hat{\omega}(T)')' \) of \( w \), the diagonal matrix \( H \) given by

\[ H_{1:4,1:4} = \text{diag} \left( \exp \left( -2\Delta(k_j' \Sigma k_j + \zeta) \right) \right), \]

\[ H_{5:N,5:N} = \text{diag} \left( \exp \left( -2\Delta(k_j' \Sigma k_j + \zeta) \right) \right), \]

and other parameters that characterize the SPDE model. It returns forecast and filter means \( m_{t_i|t_{i-1}} \) and \( m_{t_i|t_i} \) and covariance matrices \( R_{t_i|t_{i-1}}, R_{t_i|t_{i-1}}, i = 1, \ldots, T \), respectively. Note that we follow the notation of \cite{kunsch2001}. Since the matrices \( \hat{Q} \) and \( H \) are diagonal, the
covariance matrices $R_{t_i|t_i}$ and $R_{t_i|t_{i-1}}$ are also diagonal. Note that the matrix notation in Algorithm 1 is used solely for illustrational purpose. In practice, matrix vector products $(Gm_{t_i|t_{i-1}})$, matrix multiplications $(R_{t_i|t_{i-1}}H)$, and matrix inversions ($(\tau^{-2} + R_{t_i|t_{i-1}})^{-1}$) are not calculated with general purpose algorithms but elementwise since all matrices are diagonal. It follows that the computational costs for this algorithm are $O(TN)$.

The derivation of this algorithm follows from the classical Kalman filter (see, e.g., Künsch (2001)) using $\Phi'|\Phi = 1_N$, $GR_{t_i|t_{i-1}}G' = R_{t_i|t_{i-1}}GG'$, and the fact that $GG' = H$. The first equation holds true due to the orthonormality of the discrete Fourier transform. The second equation follows from the fact that $G$ is $2 \times 2$ block diagonal and that $R_{t_i|t_{i-1}}$ is diagonal with the diagonal entries being equal for each cosine - sine pair. The last equation holds true as shown in the following. Being obvious for the first four frequencies, we consider the $2 \times 2$ diagonal blocks of cosine - sine pairs:

$$
[G]'(2l-5):(2l-4),(2l-5):(2l-4)[G]''(2l-5):(2l-4),(2l-5):(2l-4) = \exp\left(-2\Delta(\mu'k_j\Sigma k_j + \zeta)\right)(\cos(\Delta\mu'k_j)1_2 - \sin(\Delta\mu'k_j)J_2)'\quad(\cos(\Delta\mu'k_j)1_2 - \sin(\Delta\mu'k_j)J_2)
$$

$$
= \exp\left(-2\Delta(\mu'k_j\Sigma k_j + \zeta)\right)(\cos(\Delta\mu'k_j)^2 + \sin(\Delta\mu'k_j)^2)1_2,
$$

$l = 5, \ldots, N/2 + 2$, which equals $[20]$. In the last equation we have used $J'_2 = -J_2$ and $J_2^2 = -I_2$.

Based on the Kalman filter, the log-likelihood is calculated as (see, e.g., Shumway and Stoffer (2000))

$$
\ell = \sum_{i=1}^{T} \log |R_{t_i|t_{i-1}} + \tau^21_N| + (\hat{w}(t_i) - m_{t_i|t_{i-1}})'(R_{t_i|t_{i-1}} + \tau^21_N)^{-1}(\hat{w}(t_i) - m_{t_i|t_{i-1}}) + \frac{TN}{2}\log(2\pi).
$$

Since the forecast covariance matrices $R_{t_i|t_{i-1}}$ are diagonal, calculation of their determinants and their inverses is trivial, and computational costs are again $O(TN)$.

**Algorithm 2 Spectral backward sampling**

**Input:** $T$, $G$, $Q$, $H$, $m_{t_i|t_{i-1}}$, $m_{t_{i-1}}$, $R_{t_i|t_i}$, $R_{t_i|t_{i-1}}$, $i = 1, \ldots, T$

**Output:** a sample $\alpha^*(t_1), \ldots, \alpha^*(t_T)$ from $[\alpha|\cdot|$

$$
\alpha^*(t_T) = m_{t_T | t_T} + (R_{t_T | t_T})^{1/2}n_T, \ n_T \sim N(0, 1_N)
$$

for $i = T - 1$ to 1 do

$$
\bar{m}_{t_i} = m_{t_i}, \ R_{t_i | t_{i-1}}^{-1} G'(\alpha^*(t_{i+1}) - m_{t_i|t_{i-1}})
$$

$$
\bar{R}_{t_i} = \left(\bar{Q}H + R_{t_{i-1} | t_{i-1}}^{-1}\right)^{-1}
$$

$$
\alpha^*(t_i) = \bar{m}_{t_i} + (\bar{R}_{t_i})^{1/2}n_i, \ n_i \sim N(0, 1_N)
$$

end for

As said, in a Bayesian context, the main difficulty consists in simulating from the full conditional of the latent coefficients $[\alpha|\cdot|$. After running the Kalman filter, this can be done with a backward sampling step. Together, these two algorithms are known as Forward Filtering Backward Sampling (FFBS). Again, backward sampling is computationally very efficient in the spectral space with costs being $O(TN)$. Algorithm 2 shows the backward sampling algorithm in the spectral space. The matrices $\bar{R}_{t_i}$ are diagonal which makes their Cholesky decomposition trivial.
4.2 Dimension Reduction and Incidence Matrix

If desired, the total computational costs can be additionally alleviated by using a reduced dimensional Fourier basis with $K \ll N$. This means that one includes only certain frequencies, typically low ones. The spectral filtering and sampling algorithms then require $O(KT)$ operations. For using the FFT, the frequencies being excluded are just set to zero. When the observation process is low-dimensional, as is the case in our application, one can include an incidence matrix $I$ that relates the process on the grid to the observation locations. Instead of (25), the model is then

$$w(t_{i+1}) = I\Phi\alpha(t_{i+1}) + \nu(t_{i+1}), \quad \nu(t_{i+1}) \sim N(0, \tau^21_N).$$

The FFT cannot be used anymore, and the total computational costs are $O(K^3T)$ due to the traditional FFBS.

5 Postprocessing Precipitation Forecasts

Nowadays, numerical weather prediction (NWP) models are capable of producing predictive fields at spatially and temporally high frequencies. Statistical postprocessing serves two purposes. First, probabilistic predictions are obtained in cases where only deterministic ones are available. Further, even if “probabilistic” forecasts in form of ensembles (Palmer 2002, Gneiting and Raftery 2005) are available, they are typically not calibrated, i.e., they are often underdispersed (Hamill and Colucci 1997). The goal of postprocessing is then to obtain calibrated and sharp predictive distributions (see Gneiting et al. (2007) for a definition of calibration and sharpness). In the case of precipitation, the need for postprocessing is particularly strong, since, despite their importance, precipitation forecasts are still not as accurate as forecasts for other meteorological quantities (Applequist et al. 2002; Stensrud and Yussouf 2007).

Several approaches for postprocessing precipitation forecasts have been proposed, including linear regression (Antolik 2000), logistic regression (Hamill et al. 2004), quantile regression (Bjørnar Bremnes 2004; Friederichs and Hense 2007), hierarchical models based on prior climatic distribution (Krzysztofowicz and Maranzano 2006), neural networks (Ramrez et al. 2005), and binning techniques (Yussouf and Stensrud 2006). Sloughter et al. (2007) propose a two-stage model to postprocess precipitation forecasts. Berrocal et al. (2008) extended the model of Sloughter et al. (2007) by accounting for spatial correlation. Kleiber et al. (2011) present a similar model that includes ensemble predictions and accounts for spatial correlation.

Except for the last two references, spatial correlation is typically not modeled in postprocessing precipitation forecasts, and none of the aforementioned models explicitly accounts for spatio-temporal dependencies. However, for temporally and spatially highly resolved data, it is necessary to account for correlation in space and time. First, spatio-temporal correlation is important, for instance, for predicting precipitation accumulation over space and time with accurate estimates of precision. Further, it is likely that errors of NWP models exhibit structured behaviour over space and time. A spatio-temporal model can capture structured dynamics of this error term and extrapolate a spatial error over time.

17
Figure 5. Locations of grid points at which predictions are obtained (50 × 100 grid of small dots) and observations stations (bold dots). Both axis are in km using the Swiss coordinate system (CH1903).

5.1 Data

We have precipitation predictions from an NWP model called COSMO-2, a high-resolution model with a grid spacing of 2.2 km that is run by MeteoSwiss as part of COonsortium for Small-scale MOdelling (COSMO) (see, e.g., Steppeler et al. [2003]). The NWP model produces deterministic forecasts once a day starting at 0:00UTC. Predictions are made for eight consecutive time periods corresponding to 24 h ahead. In the following, let \( y_F(t, s) \) denote the forecast for time \( t \) and site \( s \) made at 0:00UTC of the same day. We consider a rectangular region in northern Switzerland shown in Figure 5. The grid at which predictions are made is of size 50 × 100. Precipitation is observed at 32 stations over northern Switzerland. Figure 5 also shows the locations of the observation stations. We use three hourly data from the beginning of December 2008 till the end of March 2009. To illustrate the data, in Figure 6, observed precipitation at one station and the equally weighted areal average precipitation are plotted versus time. We will use the first three months containing 720 time points for fitting, and the last month is left aside for evaluation.

The NWP model forecasts are deterministic and ensembles are not available in our case. However, the extension to use an ensemble instead of just one member can be easily done. One can include all the ensemble members in the regression part of the model. Or, in the case of exchangeable members, one can use the location and the spread of the ensemble.

5.2 Precipitation Model for Postprocessing

The model presented in the following is a Bayesian hierarchical model (BHM). It uses the spatio-temporal process presented above at the process level. At the data stage, a model adapted to the nature of precipitation is used. A characteristic feature of precipitation is that
its distribution consists of a discrete component, indicating occurrence of precipitation, and a continuous one, determining the amount (see Figure 6). As a consequence, there are two basic statistical modeling approaches. The continuous and the discrete part are either modelled separately (Coe and Stern 1982; Wilks 1999) or together (Bell 1987; Wilks 1990; Bardossy and Plate 1992; Hutchinson 1995; Sansó and Guenni 2004). See, e.g., Sigrist et al. (2012) for a more extensive overview of precipitation models and for further details on the data model used below. Originally, the approach presented in the following goes back to Tobin (1958) who analyzed household expenditure on durable goods. For modeling precipitation, Stidd (1973) took up this idea and modified it by including a power-transformation for the non-zero part so that the model can account for skewness.

It is assumed that rainfall $y(t, s)$ at time $t$ on site $s \in \mathbb{R}^2$ depends on a latent Gaussian variable $w(t, s)$ through

$$ y(t, s) = 0, \quad \text{if } w(t, s) \leq 0, $$

$$ = w(t, s)^\lambda, \quad \text{if } w(t, s) > 0, $$

where $\lambda > 0$. A power transformation is needed since precipitation amounts are skewed and do not follow a truncated normal distribution. The latent Gaussian process $w(t, s)$ is interpreted as a precipitation potential.

The mean of the Gaussian process $w(t, s)$ is assumed to depend linearly on spatio-temporal covariates $x(t, s) \in \mathbb{R}^k$. As shown below, this mean term basically consists of the NWP forecasts. Variation that is not explained by the linear term is modeled using the Gaussian process $\xi(t, s)$ and the unstructured term $\nu(t, s)$ for microscale variability and measurement errors. The spatio-temporal process $\xi(t, s)$ has two functions. First, it captures systematic errors of the NWP in space and time and can extrapolate them over time. Second, it accounts for structured variability so that the postprocessed forecast is probabilistic and its distribution sharp and calibrated.

To be more specific concerning the covariates, similarly as in Berrocal et al. (2008), we include a transformed variable $y_F(t, s)^{1/\lambda}$ and an indicator variable $\mathbf{1}_{\{y_F(t, s)=0\}}$ which equals
An intercept is not included since the first Fourier term is constant in space. In our case, including an intercept results in weak identifiability which slows down the convergence of the MCMC algorithm used for fitting. Note that in situations where the mean is large it is advisable to include an intercept, since the coefficient of the first Fourier term is constrained by the joint prior on $\alpha$. Further, unidentifiability is unlikely to be a problem in these cases.

Concerning the spatio-temporal process $\xi(t, s)$, we apply padding. This means that we embed the 50 × 100 grid in a rectangular 200 × 200 grid. A brief prior investigation showed that the range parameters are relatively large in comparison to the spatial domain, and padding is therefore used in order to avoid spurious correlations due to periodicity. Further, we use an incidence matrix $I$ as in (27) to relate the process at the grid to the observation stations. As argued in Section 4.2, this then requires that we use a reduced dimensional Fourier expansion. I.e., instead of using $N = 200^2$ basis functions, we only use $K \ll N$ low-frequency Fourier terms. This is done for the following reasons. First, the observation stations are relatively scarce which means that there is probably no information on spatial high frequencies of the NWP error and, consequently, the low frequencies are important. Further, the covariates, i.e., the NWP forecasts, are not available on the extended 200 × 200 domain, which they need to be if we do not use an incidence matrix and model the process on the full grid.

Concerning prior distributions, we assign weakly informative, and in some cases improper, priors to the parameters $\mathbf{b}, \theta = (\rho_0, \sigma^2, \gamma, \tau, \rho_1, \mu_x, \mu_y, \lambda')'$. $\mathbf{b}$ and $\lambda$ have improper, locally uniform priors on $\mathbb{R}$ and $\mathbb{R}_+$, respectively. Based on Gelman (2006), we use improper priors for $\sigma^2$ and $\tau^2$ that are uniform on the standard deviation scale $\sigma$ and $\tau$, respectively. Further, the drift parameters $\mu_x$ and $\mu_y$ have uniform priors on $[-0.5, 0.5]$, and $\alpha$ has a uniform prior on $[0, \pi/2]$. The anisotropy parameter $\gamma$ has a uniform prior on the log scale of the interval $[0.1, 10]$. $\gamma$ is restricted to $[0.1, 10]$ since stronger anisotropy does not seem reasonable. The range parameters $\rho_0$ and $\rho_1$ as well as the damping parameter $\xi$ are assigned improper, locally uniform priors on $\mathbb{R}_+$. In summary,

$$P[b, \lambda, \theta] \propto \frac{1}{\sqrt{\sigma^2 \tau^2 \gamma}} \mathbf{1}_{\{-0.5 \leq \mu_x, \mu_y \leq 0.5\}} \mathbf{1}_{\{0 \leq \alpha \leq \pi/2\}} \mathbf{1}_{\{\lambda, \rho_0, \rho_1, \xi, \sigma^2, \tau^2 \geq 0\}} \mathbf{1}_{\{0.1 \leq \gamma \leq 10\}}.$$

### 5.3 Fitting

Monte Carlo Markov Chain (MCMC) is used to sample from the posterior distribution. To be more specific, we apply what Neal and Roberts (2006) call a Metropolis within-Gibbs algorithm which alternates between blocked Gibbs (Gelfand and Smith 1990) and Metropolis (Metropolis et al. 1953, Hastings 1970) sampling steps. For the random walk Metropolis steps, we use an adaptive algorithm (Roberts and Rosenthal 2009) meaning that the proposal covariances are successively estimated such that an optimal scaling is obtained with an acceptance rate between 0.2 and 0.3. See Roberts and Rosenthal (2001) for more information on optimal scaling for Metropolis-Hastings algorithms.
Our goal is to simulate from the posterior distribution \( [b, \lambda, \theta, \alpha, w | y] \), where \( y \) denotes the set of all observations. Note that since the latent process \( \xi \) is the Fourier transform of the coefficients \( \alpha \), knowing the posterior of \( \alpha \) is equivalent to knowing the one of \( \xi \). In the following, we use the notation "\( [y|\cdot] \)" and "\( P[y|\cdot] \)" to denote conditional distributions and densities, respectively. A Gibbs step is used to sample from \( [w|\cdot] \). To be more specific, \( w \) is only sampled for those values with corresponding observations being censored at zero or missing, the full conditionals being truncated and regular Gaussian distributions, respectively. See Sigrist et al. (2012) for more details on this type of data augmentation approach. Next, we sample jointly from \( [b, \theta, \alpha|\cdot] \) in a Metropolis-Hastings step. A proposal \((b^*, \theta^*, \alpha^*)\) is obtained by first sampling \((b^*, \theta^*)\) from a Gaussian distribution with the mean equaling the last value and an adaptively estimated proposal covariance matrix, and then sampling \( \alpha^* \) from \([\alpha|\theta^*, b^*, \cdot] \) using the forward filtering backward sampling (FFBS) (Carter and Kohn 1994; Frühwirth-Schnatter 1994). Joint sampling is preferable over iteratively and separately sampling from \( b^*, \theta^* \), and \( \alpha^* \), since these variables can be strongly dependent which results in slow mixing. In particular \( \alpha \) and \( \theta \) as well as the fixed and random effects determined by \( b \) and \( \alpha \), respectively, can be strongly dependent. This problem is similar to the one observed when doing inference for diffusion models (see, e.g., Roberts and Stramer 2001 and Golightly and Wilkinson 2008). It can be shown that the acceptance ratio for the joint proposal is

\[
\min \left( 1, \frac{P[b^*, \theta^* | w^{(i)}]}{P[b^{(i)}, \theta^{(i)} | w^{(i)}]} \right), \tag{30}
\]

where \( P[b, \theta | w^{(i)}] \) denotes the likelihood of \((b, \theta)\) given the current \( w^{(i)} \) evaluated at \((b, \theta)\), and where \( \theta^* \) and \( \theta^{(i)} \) denote the proposal and the last values, respectively. We see that this acceptance ratio does not depend on \( \alpha \). Thus, the parameters \( b \) and \( \theta \) are allowed to move faster in their parameter space. We recall that the value of the likelihood \( P[b, \theta | w^{(i)}] \) is obtained as a side product of the Kalman filter in the FFBS. Finally, for sampling from the full conditional \( [\lambda|\cdot] \), a random walk Metropolis step is used. After a burn-in of 5,000 iterations, we use 100,000 samples from the Markov chain to characterize the posterior distribution. Convergence is monitored by inspecting trace plots.

### 5.4 Model Selection and Results

As said, we use a reduced dimensional approach. The number of Fourier functions is determined based on predictive performance for the 240 time points that were set aside. We start with models including only spatial low-frequencies and add successively higher frequencies. In doing so, we only consider models that have the same resolution in each direction. For instance, we do not consider models that have higher frequency spatial basis functions in the horizontal direction than in the vertical one.

In order to assess the performance of the predictions and to choose the number of basis functions to include, we use the continuous ranked probability score (CRPS) (Matheson and Winkler 1976). The CRPS is a strictly proper scoring rule (Gneiting and Raftery 2007) that assigns a numerical value to probabilistic forecasts and assesses calibration and sharpness simultaneously (Gneiting et al. 2007a). It is defined as

\[
CRPS(F, y) = \int_{-\infty}^{\infty} (F(x) - 1_{\{y \leq x\}})^2 dx, \tag{31}
\]
where $F$ is the predictive cumulative distribution, $y$ is the observed realization, and $1$ denotes an indicator function. If a sample $y^{(1)}, \ldots, y^{(m)}$ from $F$ is available, it can be approximated by
\[
\frac{1}{m} \sum_{i=1}^{m} |y^{(i)} - y| - \frac{1}{2m^2} \sum_{i,j=1}^{m} |y^{(i)} - y^{(j)}|. \tag{32}
\]

Ideally, one would run the full MCMC algorithm at each time point $t \geq 720$, including all data up to the point, and obtain predictive distributions from this. Since this is rather time consuming, we make the following approximation. We assume that the posterior distribution of the “primary” parameters $\theta, b$, and $\lambda$ given $y_{1:t} = \{y_1, \ldots, y_t\}$ is the same for all $t \geq 720$. That is, we neglect the additional information that the observations in March give about the primary parameters. Thus, the posterior distributions of the primary parameters are calculated only once, namely on the dataset from December 2008 to February 2009. This assumption that the posterior of the primary parameters does not change with additional data may be questionable over longer time periods and when one moves away from the time period from which data is used to obtain the posterior distribution. But since all our data lies in the winter season, we think that this assumption is reasonable. If longer time periods are considered, one could use sliding training windows or model the primary parameters as non-stationary using a temporal evolution.

For each time point $t \geq 720$, we make up to 8 steps ahead forecasts corresponding to 24 hours. I.e., we sample from the predictive distribution of $y^*_{t+k}, k = 1, \ldots, 8$, given $y_{1:t} = \{y_1, \ldots, y_t\}$.

![Figure 7. Comparison of different statistical models using the continuous ranked probability score (CRPS). The unit of the CRPS is mm.](image-url)

In Figure 7, the average CRPS of the pointwise predictions and the areal predictions are shown for the different statistical models. In the left plot, the mean is taken over all stations.
and lead times, whereas the areal version is an average over all lead times. This is done for the models with different numbers of basis functions used as well as for a separable model which is obtained by setting $\mu = 0$ and $\Sigma^{-1} = 0$. Models including only a few low-frequency Fourier terms perform worse. Then the CRPS decreases successively. The model based on including $K = 29$ Fourier functions performs best. After this, adding higher frequencies results into lower predictive performance. We interpret this results in the way that the observation data does not allow for resolving high frequencies. The separable model, with $K = 29$ Fourier terms, clearly performs worse than the model with a non-separable covariance structure. Based on these findings, we decide to use the model with 29 cosine and sine functions.

Table 1 shows posterior medians as well as 95% credible intervals for the different parameters. Note that the range parameters $\rho_0$ and $\rho_1$ as well as the drift parameters $\mu_x$ and $\mu_y$ have been transformed back from the unit $[0, 1]$ scale to the original km scale. The posterior median of the variance $\sigma^2$ of the innovations of the spatio-temporal process is around 0.8. Compared to this, the nugget variance being about 0.3 is smaller. For the innovation range parameter $\rho_0$, we obtain a value of about 25 km. And the range parameter $\rho_1$ that controls the amount of diffusion or, in other words, the amount of spatio-temporal interaction, is approximately 49 km. With $\gamma$ and $\alpha$ being around 4 and 0.6, respectively, we observe anisotropy in the south-west to north-east direction. This is in line with the orography of the region, as the majority of the grid points lies between two mountain ranges: the Jura to the north-west and the Alps to the south-east. The drift points to the south-east, both parameters being rather small though. Further, the damping parameter $\zeta$ has a posterior median of about 0.01.

Next, we compare the performance of the postprocessed forecasts with the ones from the NWP model. In addition to the temporal cross-validation, we do the following cross-validation in space and time. We first remove six randomly selected stations from the data, fit the latent process to the remaining stations, and evaluate the forecasts at the stations left out. Concerning the primary parameters, i.e., all parameters except the latent process, we use the posterior obtained from the full data including all stations. This is done for computational simplicity and since this posterior is not very sensitive when excluding a few stations. Since the NWP produces 8 step ahead predictions once a day, we only consider statistical forecasts
Table 2. Comparison of NWP model and statistically postprocessed forecasts ('Stat PP') using the mean absolute error (MAE). 'Static' denotes the constant forecast obtained by using the most recently observed data. The unit of the MAE is mm.

starting at 0:00UTC. This is in contrast to the above comparison of the different statistical models for which 8 step ahead predictions were made at all time points and not just once for each day. We use the mean absolute error (MAE) for evaluating the NWP forecasts. In order to be consistent, we also generate point forecasts from the statistical predictive distributions by using medians, and then calculate the MAE for these point forecasts. In Table 2, the results are reported. For comparison, we also give the score for the static forecast that is obtained by using the most recently observed data. The postprocessed forecasts clearly perform better than the raw NWP forecasts. In addition, the postprocessed forecasts have the advantage that they provide probabilistic forecasts quantifying prediction uncertainty.

The statistical model produces a joint spatio-temporal predictive distribution that is spatially highly resolved. To illustrate the use of the model, we show several quantities in Figure 8. We consider the time point $t = 760$ and calculate predictive distributions over the next 24 hours. Predicted fields for the period $t = 761, \ldots, 768$ from the NWP are shown in the top left corner. On the right of it are pointwise medians obtained from the statistical forecasts. This is a period during which the NWP predicts too much rainfall compared to the observed data (results not shown). The figure shows how the statistical model corrects for this. For illustration, we also show one sample from the predictive distribution. To quantify prediction uncertainty, the difference between the third quartile and the median of the predictive distribution is plotted. These plots again show the growing uncertainty with increasing lead time. Other quantities of interest (not shown here), that can be easily obtained, include probabilities of precipitation occurrence or various quantiles of the distribution.

6 CONCLUSION

We have presented a spatio-temporal model and corresponding efficient algorithms for doing statistical inference for large data sets. Instead of using the covariance function, we have proposed to use a Gaussian process defined through an SPDE. The SPDE was solved using Fourier functions, and we have given a bound on the precision of the approximate solution. In the spectral space, one can use computationally efficient statistical algorithms whose computational costs grow linearly with the dimension, the total computational costs being dominated by the fast Fourier transform. The space-time Gaussian process defined through the advection-diffusion SPDE has a nonseparable covariance structure and can be physically motivated. The model is applied to postprocessing of precipitation forecasts for northern Switzerland. The postprocessed forecasts clearly outperform the raw NWP predictions. In addition, they have the advantage that they quantify prediction uncertainty.

An interesting direction for further research would be to extend the SPDE based model to allow for spatial non-stationarity. Whether this can be done using some form of basis function
Figure 8. Illustration of postprocessed spatio-temporal precipitation fields for the period $t = 761, \ldots, 768$. The figure shows the NWP forecasts (a), pointwise medians of the predictive distribution (b), one sample from the predictive distribution (c), and the differences between the third quartile and the median of the predictive distribution (d). All quantities are in mm. Note that the scales are different in different figures.
expansion approach or by relying on a discretization method such as finite differences or finite volumes remains an open question. Since the operators of the SPDE are local, one can define the SPDE on general manifolds and, in particular, on the sphere (see, e.g., Lindgren et al. (2011)). It would be interesting to investigate to which extent spectral methods can still be used.

ACKNOWLEDGMENTS

We thank Vanessa Stauch from MeteoSchweiz for providing the data and for inspiring discussions.
